1 Logistic Map

To begin understand the scaling properties in period-doubling systems, I looked at the familiar iterative map defined by

$$f_r(x) = rx(1-x).$$

As shown in IterMap.java, I used Newton's method to find out when $f_r^{(2^k)}(x_m) = x_m$. Finding the \tilde{r}_k that satisfy this condition for each k yields a sequence that must converge to the same value, r_{∞} , as the r_k which are the bifurcation points of f. To understand how $r_k \to r_{\infty}$, the ratio δ can be calculated as a scaling parameter. A similar parameter α can also be calculated, which describes the scaling of $f \to f_{r_{\inf}}$ by tracking the parameter. The calculated results are shown in the following table:

k	r_{sk}	δ	y	α
01	2.0000	_	0.5000	_
02	3.2361	_	0.8090	_
03	3.4986	4.7089	0.3836	0.7264
04	3.5546	4.6808	0.5460	2.6199
05	3.5667	4.6630	0.4817	2.5252
06	3.5692	4.6684	0.5073	2.5074
07	3.5698	4.6690	0.4971	2.5038
08	3.5699	4.6692	0.5012	2.5031
09	3.5699	4.6692	0.4995	2.5029
10	3.5699	4.6692	0.5002	2.5029

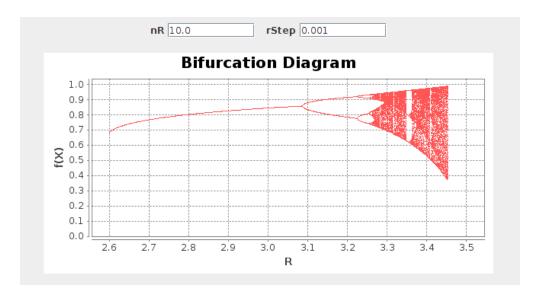

2 Universality

When the function is changed, there is no a priori reason to assume that the behavior of r and f will be the same as the logistic map. Using the function

$$G_r(x) = rx^2 \sqrt{1-x}$$

I performed the same analysis of δ and α . That these two numbers converge to the same values as for the iterative map should in fact not be surprising. The derivation of these scaling parameters revealed that for any function "like" the logistic map (single quadratic maximum, f(0) = 0) should scale like the logistic map. Thus choice of function became an irrelevant parameter. The table of δ and α are presented here, along with the bifurcation diagram for G_r . The code used to calculate these was IterMap2.java.

k	δ	α
01	_	_
02	_	_
03	4.3977	0.6785
04	4.6123	2.2768
05	4.6578	2.6430
06	4.6668	2.4575
07	4.6687	2.5228
08	4.6691	2.4953
09	4.6692	2.5060
10	4.6696	2.5017

3 Renormalization Groups

The emergent universality in the scaling of iterated maps begs the question of how odd our function can be and still behave similarly. To check this, I used a function with a 3/2 power cusp defined by

$$f(x) = r\left(\left(\frac{1}{2}\right)^{3/2} - |x - \frac{1}{2}|^{1}2\right).$$

Performing the same calculations as below yielded the table and bifurcation diagram below (see IterMap3.java):

k	δ	α
01	_	_
02	_	_
03	3.8261	0.7856
04	3.7812	3.6168
05	3.7918	3.4416
06	3.7982	3.4019
07	3.7999	3.3921
08	3.8004	3.3896
09	3.8005	3.3889
10	3.8005	3.3887

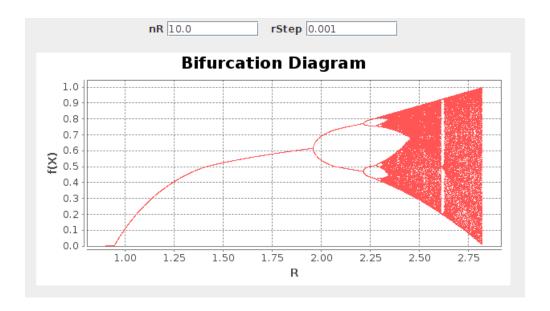

The surprising result here is that the power laws governing approach to r_{∞} are have different coefficients than for the logistic map! However, this may not be as crazy as it seems. The derivation of g(r) is the same for all functions f with a single maximum, however, there is an assumption that we used in the estimation of the scaling exponents which is no longer valid. In it, we approximated that g(z) the limiting function of f as $r \to r_{\infty}$ could be approximated as

$$g(z) \approx A + Bz^2$$

near z = 0 because of the quadratic maximum. However, this expansion is not the right expansion for g when f is the cusped function above. In this case, we must approximate

$$g(x) \approx A + B|z|^{3/2}.$$

All other assumptions that led to the Feigenbaum equation were valid, and thus we can use this minor adjustment to reevaluate our expectations for α in this new system.

Feigenbaum can take the form

$$g(z) = -\alpha g(g(-z/\alpha)).$$

With this equation and the approximation, we can write:

$$g(z) = A - B|z|^{3/2}$$

$$g(g(z)) = A - B|A - B|z|^{3/2}|^{3/2}$$

$$= A - BA^{3/2}|1 - \frac{B}{A}|z|^{3/2}$$

At this point, we can exploit the fact that z is small, and expand the term inside the absolute values as $(1+\epsilon)^{3/2} \approx 1+\frac{3}{2}\epsilon$. Doing this and substituting into the Feigenbaum eq. we find that

$$A - B|z|^{3/2} = -\alpha A + \alpha B A^{3/2} \left(1 - \frac{3B}{2A\alpha^{3/2}}|z|^{3/2}\right)$$

Equating the coefficients of like terms, we find that

$$A = -\alpha A + \alpha B A^{3/2}$$

$$\Rightarrow B A^{1/2} = \frac{1+\alpha}{\alpha}$$

$$B = \frac{3B^2 A^{1/2}}{2\alpha^{1/2}}$$

$$\Rightarrow 2\alpha^{1/2} = 3\frac{1+\alpha}{\alpha}$$

$$\therefore 0 = 9(1+\alpha)^2 - 4\alpha^3$$

Using the previously discovered value of α and NSolve.java, I numerically solved for the root of this final equation and calculated an estimate of

$$\alpha \approx 3.65$$
.

Comparing this to the value attained by iteration, we find a discrepancy of less than 10%. To improve the agreement, the approximate Feigenbaum equation could include higher order terms.

Regardless of numerical precision, the existence of a second scaling behavior supports the existence of Universality classes, which can broadly describe the behavior of certain functions that meet requirements specific to the class. Here we have seen a new universality class of functions with 3/2 power law cusps. While the period doubling and convergence to $r_{\rm inf}$ behavior are the same as for functions with quadratic maxima, the manner in which they converge differs significantly.

4 Code
